Abstract

In 1999 Pb+Au collisions at 40A GeV have been measured by the upgraded CERES/NA45 experiment at CERN-SPS. The Silicon Drift vertex detectors and the Time Projection Chamber provided the momentum determination of all produced charged particles emitted into the pseudorapidity region $2.1 < \eta < 2.6$. Neutral strange particle identification is possible via their decay into hadron channels. Pairing positive and negative tracks with the mass assumption of $p\pi$, $\pi\pi$ and KK and with some dE/dx information, the invariant mass spectrum is constructed and after subtraction of combinatorial background peaks due to Λ , K^0 and Φ are identified. Particle yields and spectra for Λ , K^0 and Φ as a function of centrality of the collision will be presented. The results will be put into perspective with the existing systematics as a function of beam energy and will be compared to the predictions of different models.
